Abstract. The ZnWO₄:Sm³⁺ compounds were prepared by hydrothermal method and characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), Raman scattering, absorption and photoluminescent (PL) techniques. This rare earth material presents high orange luminescence intensity under UV radiation. The excitation spectra of the compound presented broad bands arising from ligand-to-metal charge transfer (LMCT) (O→W and O→Sm³⁺) and narrow bands from 4f-intraconfigurational transitions. The emission spectra exhibited the 4G₅/₂→6H₉/₂ (J = 5/2, 7/2, 9/2 and 11/2) transition (direct excitation), for the system doped with Sm³⁺, while the broad band assigned to the LMCT (O→W) is observed when the excitation is monitored on the O→W LMCT state around 270 nm.

I. INTRODUCTION

Zinc tungstate (ZnWO₄) with a wolframite structure has been of practical interest for a long time because of its attractive luminescence [1]. ZnWO₄ has been applied as a possible new material for microwave amplification by stimulated emission of radiation [2], scintillator [3] and optical hole burning lattice material [4], etc. Recently, new applications for this material have emerged, including large-volume scintillators for high-energy physics [5]. Besides that, the excited tungstate group may effectively transfer energy to rare earths. In the past few years, there have been many papers concerned with the preparation and photoluminescence properties of rare earth-doped tungstates crystals [6,7]. In these, the trivalent samarium can generate red emissions in some tungstate crystals [7,8], that may make the tungstates emit blue-green light and become a potential white-light phosphor. However, Sm-doped tungstates in the forms of powder and film, especially Sm-doped ZnWO₄ material, have not been reported for the luminescence application.

ZnWO₄ has been prepared by different routes such as the Czochralski method [9], reaction in aqueous solution followed by heating of the precipitate [10], sol-gel reaction
and hydrothermal reaction over an extensive period [12]. However, ZnWO₄ particles prepared by these routes are relatively large in particle size and irregular in morphology. One of the new routes to prepare ZnWO₄ with nanometer size is hydrothermal method. Although a few studies on the chemical synthesis of zinc tungstate by the hydrothermal method have been reported, very few papers were concerned with effects of the size and morphology and Sm dopant on the optical properties of ZnWO₄ nanoparticles.

In this work, we report the synthesis of Sm doped ZnWO₄ nanopowder by hydrothermal method at a low temperature of 180°C and investigate their structure, Raman scattering, absorption and photoluminescence.

II. EXPERIMENT

Zinc tungstate (ZnWO₄) nanoparticles were prepared by the hydrothermal reaction of Zn(NO₃)₂·6H₂O, Na₂WO₄·2H₂O and Sm(NO₃)₃ at temperature of 180°C for 8 h. In a typical procedure for the preparation of sample, Zn(NO₃)₂·6H₂O (1 mmol) in water (10 ml) was added Na₂WO₄·2H₂O (1 mmol) and Sm(NO₃)₃ in water (20 ml) with vigorous stirring. H₂O was added to make 40 ml of the solution, and pH of the solution was adjusted to 6.68, respectively, with dilute of 30% NH₃·H₂O solution. The solution was then added into a Teflon-lined stainless steel autoclave of 100 ml capacity. The autoclave was heated to 180°C for 8 h without shaking or stirring. Afterwards, the autoclave was allowed to cool to room temperature gradually. The white precipitate collected was washed with distilled water four times. The solid was then heated at 80°C and dried under vacuum for 2.5 h.

Structural characterization was performed by means of X-ray diffraction using a D5005 diffractometer with Cu Kα radiation. The FE-SEM observation was carried out by using a S4800 (Hitachi) microscope. Raman measurements were performed in a back scattering geometry using Jobin Yvon T 64000 triple spectrometer equipped with a cryogenic charge-coupled device (CCD) array detector, and the 514.5 nm line of Ar ion laser. The absorption spectra were recorded by using Jasco 670 UV-vis spectrometer and the room temperature luminescent spectra were recorded on a spectrofluorometer (PL, Fluorolog-3, Jobin Yvon Inc, USA).

III. RESULT AND DISCUSSION

Fig. 1 shows the XRD patterns of Sm doped ZnWO₄ powders heated for 8 h. It is noted that the ZnWO₄ single phase could be observed in all XRD patterns. All diffraction peaks of ZnWO₄ crystal appeared when the sample was prepared at 180°C, which could be easily indexed as a pure, monoclinic wolframite tungstate structure according to the standard card (JCPDS Card number: 73-0554), except the peak at 2θ = 27° for sample with x ≥ 0.05. It was found that, the optimum temperature for the production of the high-quality crystal was as high as 180°C [13].

The SEM micrographs of the ZnWO₄ and Sm-doped ZnWO₄ powders are shown in Fig. 2, which indicates that the average particle size was about 200–500 nm for the ZnWO₄ powders and about 150–400 nm for the Sm-doped powders. It is clear that the size was decreased by the Sm substitution. This could be due to the inhibition in the crystalline growth of the powders produced by the Sm substitution. It is generally believed that this
inhibition is associated with the crystal lattice distortion resulting from the larger ionic radius of Sm$^{3+}$ (1.04 Å) compared with Zn$^{2+}$ (0.74 Å).

Fig. 3 shows a diffuse reflection spectrum of Sm doped ZnWO$_4$ nanopowder. Steep shape of the spectra indicated that the UV light absorption was due to the band-gap transition instead of the transition from the impurity level. For a crystalline semiconductor, the optical absorption near the band edge follows the equation: $a\nu = A(\nu - E_g)^{1/n}$, where $a$, $\nu$, $E_g$, and $A$ are absorption coefficient, light frequency, band gap, and a constant, respectively \cite{14}. For the ZnWO$_4$, $n$ is determined to be 2. Thus, the band gaps of the Sm doped ZnWO$_4$ nanopowders were roughly estimated to be 3.74, 3.76 and 3.79, as shown in the inset of Fig. 3. Bonanni et al. \cite{15} reported that the band gap of ZnWO$_4$ was 3.75 eV, which is in agreement to our experimental values. More further, in the spectra of Sm doped powders appears an absorption peak around 405 nm. This would originate from Sm dopant.

Fig. 4 illustrates the Raman spectra for Sm doped ZnWO$_4$ nanopowders. It is clear that, the peak shifts to higher frequency as increasing the Sm content. Studies of the optical properties and the Raman spectra of ZnWO$_4$ at room temperature have been
Fig. 3. Absorption spectra of Sm doped ZnWO$_4$ nanopowders

reported in the literature [16]. ZnWO$_4$ has the monoclinic wolframite structure with C$_{2h}$ point group symmetry and P2/c space group. It has two formula units per unit cell. The W-O interatomic distance is substantially smaller than that of Zn-O, therefore, to a first order approximation, the lattices can be separated into internal vibrations of the octahedra and the external vibrations in which an octahedron vibrates as a unit. A group theoretical calculation of the ZnWO$_4$ structure yields 36 lattices modes, of which 18 are Raman active ($8A_g + 10B_g$).

Fig. 4. Raman spectra of Sm doped ZnWO$_4$ nanopowders. The right one is the enlarged peak of 900 cm$^{-1}$.

It is assigned to the $A_g$ mode observed near 907 cm$^{-1}$ since, as in the case of the regular octahedron, the symmetric stretch is expected to have the highest frequency of all the internal modes. The $E_g$ mode (asymmetric stretch) of the regular octahedron splits into $A_g + B_g$ by the crystal field. Again, these modes are expected to have frequencies
that are higher than those of the bending mode ($T_{2g}$) of the regular octahedron. The obvious choices are the $B_g$ and $A_g$ modes observed near 786 and 709 cm$^{-1}$, respectively. The remaining modes $2A_g + B_g$ with frequencies of 407, 342 and 190 cm$^{-1}$ are assigned to the $T_{2g}$ mode of the regular octahedron.

In a first attempt to identify the six internal stretching modes of the W-O atoms in the distorted WO$_6$ octahedra of ZnWO$_4$, Liu et al. [17] assigned them to the modes at 906, 787 and 407 cm$^{-1}$ on the basis of the bond lengths and Raman frequencies in the WO$_6$ group. Afterwards, Wang et al. [18] assigned the internal stretching modes to the phonons observed near 906, 787, 709, 407, 342, and 190 cm$^{-1}$ on the basis of the temperature dependence of the Raman frequencies. However, this assignment is in contradiction with the fact that the frequencies of the internal modes are expected to be higher than those of the external modes. These authors argue in favor of their assignment that the oxygen sharing between WO$_6$ and ZnO$_6$ octahedra may cause a considerable overlap in the frequency range for the two types of vibrations. For the Sm doped powders, the peak shifts to higher wavenumber as increasing the Sm content and some new peaks appear around 600 cm$^{-1}$. This suggests the solubility of the Sm, although it can not be observed in XRD result.

Fig. 5a shows the representative PL spectra of the ZnWO$_4$ crystallites synthesized by the hydrothermal method for 8 h. With the exited wavelength at 324 nm, the corresponding emission peaks centered at $\sim$ 500 nm can be observed. This broad emission band had a shoulder in the blue region, indicating it consisted of more than one emission band. The PL spectra were fit to three peaks using a Gauss function as shown in Fig. 5a.

**Fig. 5.** (a) PL spectra of the ZnWO$_4$ synthesized by the hydrothermal method for 8 h (the solid lines are fitting results by using Gauss distribution); (b) Emission spectra of the Sm$^{3+}$ doped ZnWO$_4$ at room temperature

It is well established that the W$_6^{6-}$ complex and a slight deviation from perfect order in the crystal structure are responsible for the emission bands [19]. But there exist different opinions concerning the origin of these bands. Lammers [20] and Grigorjeva [21] believed
that the blue and green emissions originated from the intrinsic $W_6^{6-}$ complex with a double emission from one and the same center ($^3T_{1u} \rightarrow ^1A_{1g}$), whereas the yellow emission is due to recombination of e–h pairs localized at oxygen atom deficient tungstate ions. However, Ovechkin [22] ascribed the blue band to the self-trapped exciton in tungstenite crystals with strong electron–phonon coupling, and the green and yellow bands to the transitions of $T_{2u} \rightarrow T_{2g}$ and $T_{1g} \rightarrow T_{2g}$ in the $W_6^{6-}$ complex. Almost all investigations in luminescent properties of ZnWO$_4$ have been carried out for large crystals and films.

The nanosized ZnWO$_4$ prepared via a hydrothermal route in the current work showed luminescent properties similar to those of bulk ZnWO$_4$. Further studies on PL property of the as-prepared ZnWO$_4$ crystallites are in progress.

The emission spectra of the Sm$^{3+}$-doped compounds at room temperature, in the range of 500-750 nm were shown in Fig. 5b. The samples doped with Sm showed an emission typical of samarium ions. These spectra show only the bands due to 4f-4f transitions arising from the $^4G_{5/2}$ emitting level. The relatively high intensity bands are those arising from the $^4G_{5/2} \rightarrow ^6H_J$ transitions (where $J = 5/2, 7/2, 9/2$ and $11/2$), which are split in the maximum number of $(J+1/2)$ components, indicating that the Sm$^{3+}$ ion occupies a site with low symmetry. It is also observed that the forced electric dipole $^4G_{5/2} \rightarrow ^6H_{9/2}$ transition presents the highest relative emission intensity at 643 nm.

**IV. CONCLUSIONS**

In conclusion, Sm doped ZnWO$_4$ nano-particles were successfully synthesized at 180 °C by a hydrothermal route. The morphology and dimension of the ZnWO$_4$ crystallites were affected by Sm doping.

The grain size of the powders was decreased with increasing Sm content. The powders showed a broad excitation band and a broad deep blue-green emission band. The Sm substitution resulted in emissions at 568, 603 and 642 nm.
